Abstract. This paper presents: (1) the electricity and hydrogen co-production concept, (2) a thermodynamic analysis methodology for studying solid oxide and molten carbonate fuel cell hydrogen co-production, and (3) simulation results that address the impact of reformer placement in the cycle on system performance. The methodology is based on detailed thermodynamic and electrochemical principles that apply to each of the system components and the integrated cycles. Eight different cycle configurations that use fuel cell heat to drive hydrogen production in a reformer are proposed, analyzed, and compared. The specific cycle configurations include SOFC and MCFC cycles using both external and internal reforming options. The fuel cell plant performance has been evaluated on the basis of methane utilization efficiency and each component of the plant has been evaluated on the basis of second law efficiency. The analyses show that in all cases the exergy losses (irreversibilities) in the combustion chamber are the most significant losses in the cycle. Furthermore, for the same power output, the internal reformation option has the higher electrical efficiency and produces more hydrogen per unit of fuel supplied, in the case of using a SOFC.

Keywords: Solid oxide fuel cell, molten carbonate fuel cell, steam reforming, hydrogen production, thermodynamics analysis.

1. Introduction

Interest in the hydrogen economy and in fuel cells has increased dramatically in recent years. The main reason is that a hydrogen economy may be an answer to the two major challenges facing the future global economy: climate change and the security of energy supplies. Both these challenges call for development of new, highly efficient technologies that are either carbon neutral or low emitting technologies. High-temperature fuel cells, such as molten carbonate (MCFC) and solid oxide fuel cells (SOFC), are promising for the conversion of a fuel chemical energy into electricity, attaining significantly higher efficiencies compared to similarly sized energy conversion devices, such as gas turbines and internal combustion engines. Furthermore, these kinds of fuel cells produce high-temperature waste heat that can be used for cogeneration, which in this particular case is used to produce hydrogen for other uses.

The main processes for hydrogen production are presented in several literature sources (Hammerli, 1984; Ahmed and Krumpelt, 2001; Ogden, 2002; Morse, 2004). Hydrogen production types include hydrocarbon-based processes (e.g., steam reforming, partial oxidation, gasification, catalytic decomposition), non-hydrocarbon-based processes (e.g., electrolytic, thermo-chemical, photochemical, photo-electrochemical) and integrated processes that may use renewable, nuclear, or other energy inputs. Steam-methane reforming is an important and common industrial process for hydrogen production. Steam reforming produces a hydrogen-rich gas that is typically on the order of 70-75% hydrogen on a dry basis, along with smaller amounts of methane (2-6%), carbon monoxide (7-10%), and carbon dioxide (6-14%) (Lipman, 2004). Typical hydrogen production plants purify the hydrogen rich stream after steam reformation through a pressure swing absorption (PSA) or other purifying device.

The hydrogen economy, and in particular the use of hydrogen as an energy carrier for transportation applications, will depend upon local consumer access to inexpensive and environmentally sensitive pure hydrogen product delivery. Since hydrogen is challenging to store with high energy density, transport, distribution and dispensing of hydrogen typically involves a significant energy and environmental impact. In addition, the infrastructure required for transport, distribution and dispensing is likely to be expensive and require several decades to introduce. Thus, attention must be paid to developing a means of providing hydrogen to consumers in an environmentally sensitive manner.

One environmentally sensitive means of addressing both local generation of power and the production and distribution of hydrogen is to co-produce hydrogen and electricity using a high temperature stationary fuel cell system. Internal reforming high temperature fuel cells, such as solid oxide fuel cells and molten carbonate fuel cells, are developed technologies with a few commercial products available. These systems do not require hydrogen; they are instead directly fuelled by natural gas or renewable fuel such as landfill or digester gas. The natural gas is reformed either indirectly or directly in the anode compartment to produce hydrogen. Direct reformation results in both promoting hydrogen production and providing needed cooling to the fuel cell stack. Indirect reformation occurs in a separate but thermally integrated reactor. Significantly, these fuel cell systems do not electrochemically consume all the fuel that is supplied (a fundamental limitation) and they produce enough heat to reform much more than the amount of hydrogen they consume.
In this paper we present this novel concept and develop a set of integrated SOFC and MCFC cycle configurations to study the impact of reformer placement in the cycle on system performance. A comparison between eight specific cycle configurations is presented in terms of both the First Law and Second Law of Thermodynamics analyses. The fuel cell heat is used to drive hydrogen production in an endothermic reformer using both external and internal reforming strategies.

We hypothesize that the local co-production of hydrogen and electricity will produce advantages compared to traditional hydrogen production strategies (e.g., steam reformation) in three ways: (1) production will be at the point of use averting emissions and energy impacts of hydrogen transport, (2) the use of fuel cell waste heat and steam as the primary inputs for the endothermic reforming process will use less fuel, and (3) a synergistic impact of lower fuel utilization on fuel cell voltage that can be exploited to increase fuel cell electrical efficiency. One potential disadvantage of this concept is incompatibility with future CO$_2$ sequestration options that are likely to be available only in certain locations.

2. Thermodynamic Analyses Methods

2.1. Steam Reforming

A very common method of hydrogen production is the steam reforming process. Methane steam reforming consists of the reaction of methane and steam over a supported nickel catalyst at around 700ºC - 800ºC to produce a mixture of H$_2$, CO, CO$_2$ and CH$_4$. First, a global reaction mechanism is required to analyze the thermodynamics of steam reforming of a hydrocarbon fuel at a basic level (Lutz et al., 2003):

\[
C_4H_y + SxH_2O \leftrightarrow xCO_2 + (2x + 0.5y)H_2 + (S - 2)xH_2O
\]  

\(S\) is the steam-to-carbon ratio. The term “global reaction” recognizes that the above reaction is actually the net result of a series of elementary reactions, some of which include catalytic interactions with surfaces. These are of no consequence to the overall thermodynamic analyses, but they are important to understand for reactor design and efficient operation and control of reformer systems. Using Eq. (1), the formation enthalpies of the species can be added to determine the net enthalpy change as follows (Lutz et al., 2003):

\[
\Delta H_R = xh_{CO_2}^f + (S - 2)xh_{H_2O(g)}^f - h_{C_4H_y}^f + Sxh_{H_2O(g)}^f
\]

\(\Delta H_R\) is the net enthalpy change in the reaction [kJ], \(h_k^f\) is the formation enthalpy per mole of species \(k\) at standard temperature and pressure [kJ/kmol].

2.2. Chemical Equilibrium Analysis

There are two common methods used to express chemical equilibrium. One method is based on the use of equilibrium constants, while the other is based on minimization of the free energy. One of the disadvantages of using equilibrium constants is that it is more difficult to test for the presence of condensed species in the reaction products. However, it is anticipated that solid carbon may be produced during the fuel reforming process, which can deactivate the catalytic reactions. Therefore, a method based on minimization of free energy is normally used in fuel reforming analysis. Summarizing, for a given temperature (T) and pressure (P), the equations for species conservation, atoms conservation, and condensed species are, respectively (Gordon and McBride, 1994):

\[N = \sum_{k=1}^{m} N_k \quad k = 1, \ldots, m\]

\[b_l^0 = \sum_{k=1}^{m} a_{lk} N_k = b_l \quad l = 1, \ldots, l\]

\[\frac{\mu_k^0}{R_u T} + \sum_{l=1}^{l} \left( \frac{\lambda_l}{R_u T} \right) a_{lk} = 0 \quad k = m + 1, \ldots, n\]

Where: \(N\) is the molar flow [kmol/s], \(b_l^0\) is the number of atoms of element \(l\) in the reactants [kmol], \(a_{lk}\) is the number of atoms of element \(l\) in species \(k\) in the products [kmol], \(\mu_k^0\) is the molar chemical potential of species \(k\) [kJ/kmol], \(\lambda_l\) is a Lagrange multiplier, and \(R_u\) is the universal gas constant [8.314 kJ/kmol K]. Equations (3) to (5) form a set of \(n + 1\) equations that can be simultaneously solved for the unknowns \(N_k, \lambda_l,\) and \(N\). The thermodynamic function is then solved by the Newton-Raphson method for the unknowns.

2.3. High-temperature fuel cells

Applying the steady flow energy equation and assuming negligible change of kinetic and potential energy, the First Law of Thermodynamics and the entropy balance for a fuel cell system can be written as (Chan and Xia, 2002;
Kanamura et al., 1991; Takehara et al., 1989):

\[ Q_{cv} - W_{cv} + \sum_{k} (N_k h_k)_R - \sum_{k} (N_k h_k)_P = 0 \]  
\[ \frac{Q_{cv}}{T} - \sum_{k} (N_k s_k)_R - \sum_{k} (N_k s_k)_P + S_{cv} = 0 \]

Where: \( Q_{cv} \) is heat in a control volume [kW], \( W_{cv} \) is work in a control volume [kW], and \( S_{cv} \) is entropy production in a control volume [kW/K]. The molar enthalpy \( (h) \) and entropy \( (s) \) of each component at a temperature \( T \) in a mixture of gases is calculated as (Herle et al., 2004):

\[
h_k = h_k^f + \int \frac{T}{298 K} Cp_k dT
\]
\[
s_k = s_k^0 + \int \frac{T}{298 K} Cp_k dT - R_u \ln \left( \frac{P_k}{P^0} \right)
\]

\( Cp_k \) is the temperature-dependent specific heat capacity of component \( k \). The Nernst equation for a MCFC and SOFC is given by (EG&G Technical Services, 2002):

\[
\text{MCFC: } E = E_0 + \frac{R_u T}{n_e F} \ln \left[ \frac{P_{H_2} P_{O_2}^{0.5}}{P_{H_2} O} P_{CO_2, \text{cathode}} \right] \quad \text{SOFC: } E = E_0 - \frac{R_u T}{n_e F} \ln \left[ \frac{P_{H_2} P_{O_2}^{0.5}}{P_{H_2} O} \right]
\]

Where: \( E_0 \) is the ideal standard potential [V], \( n_e \) is the number of participating electrons in the reaction [mol/e/mol], \( F \) is Faraday’s constant [96,487 kC/kmol], and \( P_k \) is the partial pressure of the element \( k \) [MPa]. Voltage (V) can be calculated as (Chan et al., 2001):

\[ V = E - \eta_{\text{act}} - \eta_{\text{conc}} - \eta_{\text{ohm}} \]
\[ \eta_{\text{act}} = \frac{R_u T}{\alpha n_e F} \ln \left( \frac{J}{J_0} \right) \quad \eta_{\text{conc}} = \frac{R_u T}{n_e F} \ln \left[ 1 - \frac{J}{J_L} \right] \quad \eta_{\text{ohm}} = j R_{\text{int}} \]

Where: \( \eta_{\text{act}} \) is the activation polarization [V], \( \eta_{\text{conc}} \) is the concentration polarization [V], and \( \eta_{\text{ohm}} \) is Ohmic polarization [V]. \( \alpha \) is the transfer coefficient [-]. \( j \) is the operating current density [A/m²], \( J_0 \) is the exchange current density [A/m²], \( J_L \) is the limiting current density [A/m²] and \( R_{\text{int}} \) is the internal resistance [Ω m²]. The total exergy of a flow \( (E_{\text{TOT}}) \) consisting of many components (neglecting the magnetic, electric and nuclear effects) is given by (Utgikar et al., 1995):

\[ E_{\text{TOT}} = E_{\text{TM}} + E_{\text{CH}} \]
\[ E_{\text{TM}} = \sum_{k=1}^{n} N_k (h_k - h_k^0) - T_0 \sum_{k=1}^{n} N_k (s_k - s_k^0) \]
\[ E_{\text{CH}} = \sum_{k=1}^{n} x_k E_{\text{ch},k} + m R_u T_0 \sum_{k=1}^{n} x_k \ln x_k \]

Where: \( E_{\text{TM}} \) is thermomechanical exergy [kW], \( E_{\text{CH}} \) is chemical exergy [kW], \( x_k \) is the molar fraction of the element \( k \) in the composition [-], \( m \) is the mass flow [kg/s] and 0 denotes for standard. Exergy analysis requires that the environment is defined. The temperature and pressure of the environment were set equal to the reference temperature and pressure (298 K, 0.101 MPa) in the current work. The atmosphere was modeled as an ideal-gas mixture with the composition shown in Table 1 (Bedringås et al., 1997).

Table 1 - Mole fractions and chemical exergy of the reference components in atmospheric air (Bedringås et al., 1997).

The fuel utilization efficiency (\( \varepsilon_F \)) is the ratio of all the useful energy extracted from the system (electrical \( (W_{el}) \) and process heat \( (Q_P) \)) to the thermal energy of the input fuel \( (E_F) \). Thus (Utgikar et al., 1995):

\[ \varepsilon_F = \frac{W_{el} + Q_P}{E_F} \]
The second law efficiency ($\epsilon_{II}$) may be defined as the ratio of the amount of exergy of products to the amount of exergy supplied ($E_{x}$). This parameter is a more accurate measure of the thermodynamic performance of the system. Thus (Utgikar et al., 1995):

$$\epsilon_{II} = \frac{W_{el} + E_{xp}}{E_{x}}$$  \hspace{1cm} (16)

3. Cycle Configurations

A solid oxide and molten carbonate fuel cell system can be configured in many ways. Cycle configurations that include the potential for hydrogen co-production can be even more complex. In the current paper we present several possible generic cycle configurations that are considered for their potential electricity and hydrogen co-production capabilities. The detailed thermodynamic and electrochemical analyses are accomplished on these eight specific cycle configurations, which use the high temperature fuel cell heat to drive hydrogen production in a reformer. Cycle configurations that consider both external and internal reforming options have been developed as shown in Figures 1, 2 and 3. Figures 1 and 2 shows the SOFC options. Figure 1 shows the external reformer cycle configurations with the hydrogen production reformer placed in different positions in the cycle for each of the configurations 1-4. Figure 2 presents: (a) a different configuration for external reforming (with combustion chamber after the air pre-heater), and (b) the internal reforming case. Figure 3 shows the MCFC options: (a) the external reformer cycle configuration (config. 7), and (b) the internal reforming case (config. 8). These generic cycle configurations were developed to examine the general impacts of system design on the thermodynamic performance of high-temperature fuel cells cycles for hydrogen and electricity production. Each of the cycles contains pre-heaters for methane fuel preheat, air preheat, and water boiling and preheat. Each configuration also contains a reformer and combustor. In all of the cases, the thermodynamic analyses use the equations presented above, which comprise primarily overall energy and exergy analyses.

Figure 1. SOFC configurations 1 to 4 (these configurations consist of the placement of a reformer: (1) after the air preheater, (2) after the water preheater, (3) after the methane preheater, and (4) after the combustion chamber).

Figure 2. SOFC configurations 5 and 6: (a) External reforming with combustion chamber after the air preheater (5) and (b) Internal reforming option (6).
6. Results and Discussion

The following considerations and assumptions are made for the analyses presented herein:

- Fuel cell electrical power output is 1,000 kW.
- Solid oxide fuel cell operating temperature is 1000ºC (EG&G Technical Services, 2002).
- Molten carbonate fuel cell operating temperature is 650ºC (Selman, 1993).
- Pre-heaters are 90% efficient and heat exchanger is 85% efficient (Iwahashi et al., 1998).
- Fuel utilization in the anode compartment and oxidant utilization in the cathode compartment is 75% and 25%, respectively, in the molten carbonate fuel cell unit (Selman, 1993).
- Fuel utilization in the anode compartment and oxidant utilization in the cathode compartment is 85% and 25%, respectively, in the solid oxide fuel cell unit (Larminie and Dicks, 2003).
- All gas stream pressures are atmospheric (Dunbar et al., 1991).

Figure 4 shows the results of the overall energy analysis for all eight cycle configurations and Fig. 5 shows the results of overall exergy analyses for each of the eight configurations for a fixed steam-to-carbon ratio of 2. Figure 4 shows that the overall thermodynamic efficiency of these types of integrated hydrogen and electricity producing cycles is very high. For all configurations (except #5) overall efficiencies are greater than 59%. Note that this efficiency is a “mixed” efficiency that includes electrical work and chemical energy of the hydrogen produced in the numerator. For clarity, the contributions of electricity and hydrogen energy (thermal) are each presented for all of the cases.

When comparing the energy analyses amongst cycle configurations, Fig. 4 indicates that for the same amount of power produced by the fuel cell, configuration 6 (internal reforming SOFC) shows the highest potential for production of hydrogen (about 3.2 g/s for S = 2 and 3.3 g/s for S = 3) as well as the highest overall efficiency. Also, configuration 6 achieves a remarkable overall efficiency of nearly 80% for the steam-to-carbon ratio of 3. One of the reasons for this high efficiency is the synergy associated with internal reformation that is reflected in the higher electrical efficiencies for configuration 6. These higher electrical efficiencies are due to the higher exit hydrogen concentration in the fuel cell for configuration 6 leading to higher voltage potential.

Figure 4 shows that configuration 5 (combustion chamber after the air pre-heater) is the worst cycle configuration with the highest thermal losses on an energy basis. However, configuration 5 may be the most flexible configuration with regard to hydrogen production capacity (not studied in the current work). Configurations 1, 2, and 3 perform similarly with regard to hydrogen production and efficiency, but configuration 1 is slightly less efficient with lower hydrogen production capability. Also, it can be observed in Fig. 4 that the highest hydrogen production for a MCFC occurs with the configuration with uses a reformer separated from the fuel cell (external reforming) while for a SOFC the internal reforming option provided the best results.

Figure 5 presents the exergy analyses for all of the configurations, indicating the components that contribute most significantly to losses within each configuration. Components with high irreversibilities or low second law efficiency and the manner in which they are implemented in the cycle are those that designers should focus upon to improve system performance.

The exergy results of Fig. 5 show that the major destruction of exergy (irreversibility) was in the combustion chamber (CC) for all configurations. In all cases the combustion chamber is associated with the maximum temperature of the products in the integrated fuel cell system. Since the irreversibility in the combustion chamber is much larger than the other component irreversibilities the values for combustion chamber irreversibility are provide at the top of Fig. 5 for each configuration.
Figure 4. Results of energy performance analysis.

Figure 5. Results of exergy performance analyses (lines for efficiency, bars for irreversibilities).
Several interesting results emerge from the second law analyses presented in Fig. 5. The variations in second law performance amongst the cycle configurations are primarily associated with the combustor, fuel preheater, and reformer components. The combustor irreversibility of the MCFC configurations is lower than the SOFC configurations because the lower temperature of reactants and the lower temperature difference between reactants and products (maximum of 350º for MCFC and maximum of 500º for SOFC). In the configurations 6 and 8, the product hydrogen is removed before the combustor. Hydrogen contributes to two moles of water for every mole of oxygen converted in the combustor compared to one mole for every mole of carbon converted to CO₂. Thus removal of hydrogen from the inlet stream of the combustor leads to a lower number of moles in the product stream and the lowest combustor exit exergy compared to cases with hydrogen in the inlet gases. However, inlet exergy for the internal reforming case (configurations 6 and 8) is substantially lower than those of the other cases leading to lower second law efficiency for the combustor. The second law efficiency for the combustor between the MCFC configurations is similar. However, among the SOFC configurations, configuration 5 has irreversibility in the combustion chamber that is similar to configurations 1-4. The second law efficiency of the combustion chamber of configuration 5 is the lowest of all configurations due to the high temperature rise in this component placed after all of the pre-heaters. All other cases have similar second law efficiency and irreversibilities in the combustor.

In the external reforming MCFC cases, the fuel/water preheater heated up water and methane (using more fuel) that causes the value for irreversibilities be higher than those for internal reformation. Also, the second law efficiency for the water preheater in the external reforming case is lower than in the internal reforming case (25% versus 48%).

The fuel preheater irreversibility for configuration 5 is higher and its second law efficiency is lower compared to all of the other configurations. This is due to the high hydrogen content of the stream entering this pre-heater for this case, since the chemical exergy of hydrogen is high compared to the water that is present in this stream for the other configurations. Configuration 5, which shows the worst energy and hydrogen production performance, has better exergy performance in the reformer component than all the other cycle configurations because the combustor is placed immediately before the reformer leading to a better reformer operating temperature. Configuration 6 has the second highest reformer second law efficiency, also due to a better resulting reformer operating temperature. The reformer of configuration 6 operates at the 1000º C temperature of the SOFC, which results in good conversion of fuel to hydrogen as indicated in Fig. 4. The reformer performance of configuration 6 also benefits from concurrent electrochemical and chemical reactions in the anode compartment.

The second law efficiency (and exergy losses) in the fuel cell component is very similar in each of the cycle configurations. The difference in second law efficiency for the fuel cell configurations is slight, varying from 30% to 35%. The fuel cell irreversibility of configuration 7 is about 15% higher than configurations 1 to 5 primarily due to higher fuel throughput for the same power output. The fuel cell irreversibility difference between configurations 7 and 6 is only of 3%.

The overall second law efficiency of configuration 1 is highest and configuration 7 is lowest among all the configurations considered. The second law efficiency of configuration 1 is high due to cumulative better exergy performance of the components as integrated in configuration 1. This is primarily manifested in lower irreversibilities in the fuel cell (compared to configuration 1 and 8), and the reformer (compared to all other configurations except configurations 6 and 7). Among the SOFC configurations, configuration 6, which shows the best energy performance and hydrogen production capacity, exhibits the worst exergy performance due to a higher inlet exergy requirement. That is, more fuel is required to achieve the higher hydrogen production of configuration 6. However, what this result indicates is that there is the potential for significant performance improvements for the internal reforming option of configuration 6. These potential improvements will be addressed in future studies.

To directly compare the proposed concept to stand-alone steam reformation one final set of calculations was performed. Strict hydrogen production thermal efficiency was calculated on the basis of hydrogen energy out divided by the fraction of methane fuel input that was used to produce the hydrogen. That is, the quantity of fuel that directly produces electricity (in the fuel cell) was subtracted out of the denominator. The resulting strict hydrogen production efficiency of configurations 1 through 8, for steam-to-carbon ratio of 2.0, were 85.6%, 84.2%, 84.3%, 83.7%, 60.8%, 85.6%, 81.6%, and 89.6%, respectively. These thermal efficiency values, except for the configuration 5 value of 60.8%, are clearly superior to typical small-scale steam reformation [Ogden, 2002] and even compete with large-scale steam methane reforming efficiencies reported in the range of 75 to 80% [Ogden, 2002].

Further research is justified using the insight gained through the present investigation. This research should focus on those subprocesses having large exergy losses and should include, for example, process integration, design and optimization, temperature profile changes, etc.

6. Summary and Conclusions

The high efficiency and lower pollutant emission features of fuel cells compared to other technologies make them an attractive technology for energy generation. Hydrogen is one of the most abundant elements in our universe, but it is difficult to obtain in its pure form. Hydrogen is also difficult to store and transport due to its low volumetric energy density. Thus, novel means of hydrogen production, distribution, and delivery are required. Hydrogen can be extracted from water or hydrocarbons using chemical or electrochemical processes. There are relatively simple procedures for
obtaining hydrogen from both of these sources, but both require a significant amount of energy. A very common method of hydrogen production is the steam reforming of natural gas.

This paper presents a novel method for the local co-production of hydrogen and electricity from high temperature fuel cells. Several generic cycle configurations are presented. In addition, a methodology for analyzing this concept is presented that includes thermodynamic and electrochemical analyses. The energy analyses of these cycles show that the configuration in which the fuel is reformed inside of the solid oxide fuel cell has the best energy efficiency and co-production of hydrogen capacity. However, the exergy analysis of this same configuration shows that much effort should be invested to further improve this cycle configuration. The electrical efficiency (ratio of the electric energy produced to the fuel thermal energy) of the systems was about 41 to 49%, showing the highest value for the internal reforming molten carbonate fuel cell. The overall energy efficiency (ratio of the electric energy and hydrogen produced to the fuel thermal energy) ranges from 45% to 80%. The lowest overall energy efficiency was for a case that combusted fuel in the exhaust of the solid oxide fuel cell system for hydrogen production in an external reformer. The highest overall efficiency was for the internal reforming solid oxide configuration.

The hydrogen co-production concept presented in this paper is clearly worthy of further investigation, development, and demonstration. Thermodynamic analyses suggest a clear advantage of net fuel savings compared to separate generation of electricity and hydrogen, which is only augmented by the avoidance of transport energy and emissions benefits. Fuel cell technology is advancing with several commercial products emerging into the market that may become amenable to testing the hydrogen co-production concept. But significant challenges remain, including the need for more robust high temperature fuel cells that can internally reform methane-based fuels, integration with small-scale hydrogen separation, compression and storage technology, and cost reduction.
